Abstract

Double localization of tuberculosis is a rare finding among immunocompetent patients. Intestinal tuberculosis is a rare condition and its diagnosis remains a challenge to the physician. We present the case of a 21 year old male patient with intestinal tuberculosis in which the first manifestation was an acute appendicitis. Ultrasound findings were an abscessed appendicular mass. The surgical intervention found a granulomatous aspect of the peritoneum and total necrosis of the appendix. Histopathological examination confirmed the diagnosis and the pulmonary radiography detected the concomitant pulmonary tuberculosis.

Keywords: tuberculosis; appendicitis; ultrasonography

Introduction

Tuberculosis (TB) remains a major global health problem, with high morbidity and mortality, especially in underdeveloped countries [1,2]. Out of the total TB cases, only 10-12% cases are extrapulmonary TB [3]. The ileocecal region is affected in 64-75% of cases of gastrointestinal TB, followed by the jejunum, and colon [4,5], mainly in young adults with a slight female predominance [6]. There are no specific clinical and radiological findings, so the final diagnosis is possible in the majority of cases only after histopathological examination [4]. TB with double localization is a rare condition, found mainly in patients with low immunity status or pregnancy, and respiratory symptomatology is the most important.

We report the case of a young male with TB appendicitis as a rare cause of abdominal pain.

Case report

A 21 year old male patient was admitted in the emergency room with constant and moderate lower abdominal pain, especially in the right iliac fossa, diarrhea (3-4 stools/day) and fever (up to 38°C). The symptoms started two months prior presentation when the symptomatology was interpreted by the general practitioner as enterocolitis and was treated with antibiotics (fluoroquinolones), but no amelioration was obtained. At presentation a moderate painful abdominal mass in the lower right quadrant was palpated but without a peritoneal reaction. An elevated white cell count with neutrophilia was found, but no other lab alterations.

Ultrasonography performed with a 3.5 MHz transducer on Esaote Mylab 50 XVision found a 4 cm isoechoic mass with a hypoechoic center in the lower right abdominal quadrant, with inflamed surrounding ileum and jejunum. Slightly hypervascularisation of the affected intestinal wall on Doppler examination and minimal ascites were also noted (fig 1).

As the pain became more intense, and an acute diverticulitis could not be excluded, no endoscopic investigations were performed. Computed tomography showed in hypogastrium towards the right inguinal fossa a mass with high contrast agent capture and a liquid center, with a small lateral cystic-like zone. An abscess was concluded, which could involve the appendicular area (fig 2).

An acute appendicitis with appendicular block was concluded and antibiotics were prescribed. (ceftazidime 3 grams and metronidazole 1 gram daily). The white cell count continued to grow (12.610/µl), with low lympho-
cytes (1.640/µl) and high neutrophils (9.220/µl). Also, liver transaminases elevated, a prolonged prothrombin time (19.9 seconds), and a high inflammatory status (erythrocyte sedimentation rate=50 mm/h, high sensitive C-reactive protein=12 mg/L) were noted in laboratory tests. As biological and clinical status did not improve, appendectomy was decided. The surgical intervention found the peritoneum, the entire abdominal serosa and the greater omentum covered in miliary like lesions. In the right iliac fossa, an inflammatory block was found in which the appendix, cecum, sigmoid, and the last ileal ansa were caught. At the extracorporeal dissection, a small quantity of pus was revealed and the appendix with total necrosis was observed.

Histopathological analysis (including the peritoneal miliary lesions) showed granulomatous inflammation with caseous necrosis and ascites and pus samples were positive for bacillary infection (fig 3).

Pulmonary radiography found specific small lesions in the right upper lobe and the sputum culture exam was positive for Mycobacterium Tuberculosis (the primary lesion). No alteration of the immunological status was found. The specific tuberculostatic treatment was started with normalization of the laboratory tests in two weeks and progressive improvement of the health status.

Discussions

Our patient was a young immunocompetent male, with double localization of TB (pulmonary and intestinal). The appendicitis was the first manifestation, without any pulmonary symptomatology.

Intestinal TB represents 11-16% of extrapulmonary TB and can occur as a primary (bacillus ingestion) or a secondary infection, when the lung is first affected. The dissemination can be haematogenous, through the lymphatic channel or from the adjacent foci [7,8]. TB appendicitis is a rare condition (about 0.1-0.2% of all acute appendicitis) and has no specific symptoms [9,10]. Our patient had a subacute onset. Other published cases showed different types of onset of TB appendicitis, either acute, moreover with classical appendicitis signs [11], or subacute, the rarest, with appendiceal mass, often treated for acute gastroenteritis [12]. Most frequent symptoms cited are weight loss, weakness, lack of appetite, along with uncharacteristic abdominal pain, as our patient [13]. Anti-tuberculous treatment must be initiated early for a good outcome [14].

Double localization of TB occurs mainly in immunological impaired patients with important symptomatology (weight loss, hemoptysis, acute surgical abdomen). Unspecific findings in early abdominal TB include a hypoechogetic mural thickening of the ileal folds (6 to 10 mm) with hypervascularization at Doppler examination along with thickened mesentery (up to 45 mm, due to fat deposition) and lymph nodes (up to 30 mm, with hypoechoic center due to caseation necrosis), and low quantities of ascites. A non-compressible adynamic appendix with the loss of inner layers could be signs of acute appendicitis. If perforated, pericaecal fluid, loss of the echogenic submucosa or generalized adynamic ileus is observed. Hyperperistalsis of the affected area can rarely be observed [15-17]. In HIV patients, spleen involvement is common (hypoechoic lesions) [18]. All the removed ap-
Appendixes should be histopathologically examined, as TB appendicitis can be established only after Ziehl-Neelsen or direct hematoxylin-eosin colorations [19].

Ultrasound diagnosis of TB appendicitis is very difficult and must always be correlated with clinical manifestations. Even if the first symptoms can mimic other diseases, TB should be considered in high TB prevalence areas until otherwise ruled out.
